Abstract

We explore the dark matter sector in extensions of the Minimal Supersymmetric Standard Model (MSSM) that can provide a good fit to the PAMELA cosmic ray positron excess, while at the same time addressing the little hierarchy problem of the MSSM. Adding a singlet Higgs superfield, S , can account for the observed positron excess, as recently discussed in the literature, but we point out that it requires a fine-tuned choice for the parameters of the model. We find that including an additional singlet, Ψ , allows both a reduction of the weak-scale fine-tuning, and an interpretation of the cosmic ray observations in terms of dark matter annihilations in the galactic halo. Our setup contains a light axion, but does not require light CP-even scalars in the spectrum.

I. INTRODUCTION

A. Dark Matter and Cosmology

Within the standard Λ Cold Dark Matter cosmological model (Λ CDM), which reproduces the available experimental observations with remarkable success, about a fifth of the energy density in the universe is contributed by dark matter (DM) [1]. The DM cannot be in the form of ordinary baryonic matter as deduced from considerations of cosmological nucleosynthesis and observations of the anisotropies of the cosmic microwave background (CMB). Despite constituting most of the mass in the universe and playing a crucial role in the growth and dynamics of structure, either the lack of appreciable interactions with observable particles or its mass have so far prevented the determination of its origin and composition.

On the other hand, elementary particle theory provides several candidates for the DM, such as Weakly Interacting Massive Particles (WIMPs). What makes WIMPs attractive DM candidates is that their existence is motivated *independently* in particle physics extensions that address some of the shortcomings of the Standard Model. For instance, one of the by-products in extensions relying on low energy supersymmetry (SUSY) to alleviate the hierarchy problem in the higgs sector of the SM, is the natural occurrence of a stable WIMP. The neutralino in the Minimal Supersymmetric Standard Model (MSSM) is the simplest viable example. By virtue of its weak interactions, the thermal relic density of a WIMP is of the right order of magnitude, and its existence can be probed through both direct and indirect detection experiments (see e.g. [2, 3] for reviews).

Although no convincing signal has yet been found, the latest PAMELA data [4, 5], suggesting a new source of galactic positrons, has been interpreted as the result of annihilation of DM particles in the galactic halo [6–19] or DM decay [20–25].

On the other hand, several astrophysical sources such as pulsars [26–28], supernova remnants [29, 30], or secondary production in regions where cosmic rays are accelerated [31–34] may also account for part of, or perhaps all, of the observed fluxes. In addition, the hard injection spectrum required to fit the positron fraction measured by PAMELA, and the non-observation of an equivalent anti-proton excess [35] exclude annihilation of thermal WIMPs, such as the neutralino in the MSSM, as a viable explanation.

A DM interpretation of the data demands that the particles making up the dark galactic halo annihilate mostly to charged leptons with a cross-section which is $\sim 10 - 100$ times larger than the canonical value leading to the correct cosmological abundance via thermal decoupling [36], $\langle\sigma v\rangle_{\text{ann}} \approx 3 \times 10^{-26} \text{ cm}^3 \text{ s}$. MSSM neutralinos could annihilate primarily to leptons, either due to radiative corrections in a small region of parameter space [37], or for a wino-like LSP of about 200 GeV as discussed in [38], although a non-standard cosmological evolution has to be invoked to explain the *boosted* annihilation cross-section required by observations. A nearby clump of DM could raise the annihilation rate [39], but it is highly unlikely that a sufficiently large clump can be found in the solar neighborhood [40]. The generic expectation in the MSSM is that neutralinos annihilate to a mixture of heavy quarks and Higgs bosons producing a spectrum that is too soft to account for the PAMELA data, while also over-producing anti-protons [41].

Several alternative particle physics scenarios have been proposed that predict DM particles can explain the rise in the positron flux at high energies without conflicting with other measurements. For instance, if the DM particles annihilate with a weak-scale strength to light metastable mediators which are very weakly coupled to the Standard Model, then kinematical constraints preclude any final states other than light leptons. In addition, the exchange of light mediators results in long-range interactions that enhance the annihilation cross-section when the DM particles are moving at non-relativistic velocities, as is the case for present day processes occurring in the galactic halo. This so-called Sommerfeld enhancement [9, 42, 43], reconciles the required underlying weak-scale interaction at the time of DM freeze-out that generates the correct relic abundance with a much larger annihilation cross-section in the present galactic environment. The scenarios in [9, 12, 44], among others, provide particular implementations of these principles, but they are not primarily motivated by a solution of the hierarchy problem.

B. Natural Models of Dark Matter

In this paper, we seek a model of dark matter that addresses the hierarchy problem and other naturalness constraints while still generating the fluxes observed by PAMELA. We require the following

- Stable dark matter with a mass of 100 GeV or above.

- Dark matter annihilations dominantly to light leptons.
- Solution to the hierarchy problem.
- Minimal fine-tuning among model parameters.
- Thermally generated dark matter.
- Passes constraints from accelerators.

We find that this set of requirements will place severe restrictions on the form of the model.

We begin with a consideration of naturalness in supersymmetric models. The MSSM, while solving some problems of the Standard Model, introduces new theoretical problems that suggest it might not be a complete description of physics at the electroweak scale. It must contain a mass term μ for the two Higgs doublets, $\hat{H}_u$ and $\hat{H}_d$, which can neither vanish nor be naturally large ($\sim M_{GUT}$ or $\sim M_{Pl}$) for phenomenological reasons. The lack of an explanation of $\mu \approx M_{Susy}$ constitutes the μ -problem of the MSSM [45]. The addition of a singlet chiral superfield, $\hat{S}$, to the particle content of the MSSM provides an elegant solution to the μ -problem: the scalar component of $\hat{S}$ obtains a vacuum expectation value (vev) of the right order, dynamically generating the mass term μ .

Another challenge to these models is that the non-observation of the Higgs boson at LEP-II requires large soft-supersymmetry-breaking mass parameters to raise the mass of the lightest CP-even Higgs above the tree-level prediction, $m_h < m_Z$, in the MSSM. The discrepancy between the large size of these soft SUSY breaking terms compared to their natural scale, the electroweak scale, is known as the little-hierarchy problem. Here again, the scalar components of $\hat{S}$, that mix with the neutral scalar components of $\hat{H}_u$ and $\hat{H}_d$, can alleviate the little fine-tuning problem of the MSSM [46–48] by lifting the Higgs mass or allowing for new Higgs decay modes that weaken the LEP-II limits [48–50]. The resulting model is the Next-to-Minimal Supersymmetric Standard Model (NMSSM, see e.g. [51, 52] for recent reviews), and its dark sector can differ considerably from that of the MSSM. Much like in the Higgs sector, mixings with the fermionic component of $\hat{S}$, the singlino, result in an extended neutralino sector. The lightest neutralino can have a sizeable singlino component and, if it is the LSP, the expected signatures at colliders and the DM phenomenology could markedly differ from the minimal scenario.

Interestingly, it has been pointed out that the positron excess observed by PAMELA can be explained by neutralino annihilation in the NMSSM [16–18]. The richer Higgs and neutralino sectors can potentially accommodate the ingredients shown in [9, 12, 44] to result in enhanced mostly leptonic fluxes. The fact that this scenario is motivated independently from particle physics considerations as outlined above, makes it even more appealing. It is this last point that we set forth to study in this paper. We revisit in Section II the region in the NMSSM parameter space that allows for an explanation of the reported cosmic-ray anomalies in terms of neutralino annihilations, and study whether the original motivation of naturally addressing the little higgs and μ -problem is preserved. Our findings show that this is not generically possible without accidental relations among the parameters, losing the naturalness motivation. In Section III we add another singlet superfield, $\hat{\Psi}$, to the dark sector, which suffices to avoid reintroducing fine-tunings in the electroweak sector. A study of a similar model, with vector-like dark matter, was presented in [12] in the context of an axionic sector. Here we do not require a light singlet scalar to generate a Sommerfeld enhancement, as we take a light pseudoscalar to be sufficient. We study the dark matter sector in Section V and we find somewhat different behavior in our scenario than the one presented in [12] regarding the behavior of the extended NMSSM model. Our results are summarized in Section VI.

II. DARK MATTER PHENOMENOLOGY IN SINGLET EXTENSIONS OF THE MSSM

In supersymmetric extensions of the SM the masses of the up-type quarks and down-type quarks are generated by the vevs of two Higgs SU(2)-doublets H_u and H_d . With this minimal field content in the Higgs sector, as found in the MSSM, a dimension-full coupling $\mu \hat{H}_u \hat{H}_v$ must be appear in the superpotential. For phenomenological reasons the parameter μ has to be of the order of the electroweak breaking scale, v_{EW} , which is orders of magnitude below the natural value in the MSSM, $\mu \sim \Lambda$, where Λ represents the ultra-violet (UV) cut-off of the theory (GUT or Planck scale). In the NMSSM (see e.g. [51, 52] for recent reviews and further references), the mass term μ is replaced by the vev of a scalar field – induced by the soft SUSY breaking terms – which has a Yukawa coupling to the Higgs doublets. The

simplest scenario allows only scale-invariant and renormalizable terms in the superpotential:

$$W = \lambda \hat{S} \hat{H}_u \hat{H}_d + \frac{\kappa}{3} \hat{S}^3, \quad (1)$$

where λ, κ are dimensionless, and we have not included couplings to the lepton and quark matter fields of the MSSM, which are not relevant here. Electroweak symmetry breaking generates vevs for the scalar components of both MSSM Higgs superfields, $\hat{H}_u$ and $\hat{H}_d$, as well as a vev $\langle S \rangle$ for $\hat{S}$ of the order of the weak scale. In this way the NMSSM generates an effective μ parameter,

$$\mu = \lambda \langle S \rangle, \quad (2)$$

of the order of the weak scale, $v_{\text{EW}} \approx 174$ GeV, which solves the μ -problem of the MSSM. The scalar components of $\hat{S}$ mix with the neutral scalar components of $\hat{H}_u$ and $\hat{H}_d$, and this results (in the absence of explicit CP violation) in three CP-even and two CP-odd neutral scalars. Mixing of the fermionic components of $\hat{S}$ with the neutral higgsinos and gauginos leads to five neutralinos in the spectrum of the NMSSM. The tree level Higgs and neutralino mass matrices can be found in e.g. [51, 52], or deduced from the expressions in Section III by taking the limit $\xi, A_\xi \rightarrow 0$.

As mentioned above, the richer Higgs sector in the NMSSM allows for a resolution of the little fine-tuning problem of the MSSM [48–50, 53]. In addition, the appearance of new Higgs decay modes, together with a possible singlino component, can result in a markedly different phenomenology for the light neutralino, which is a candidate for DM as in the MSSM. Interestingly, it has been pointed out by several groups that an explanation of the anomalous cosmic-ray fluxes reported by PAMELA in terms of NMSSM neutralino annihilations is possible.

In the scenario envisaged in [16], the LSP is a neutralino of the bino-type with Higgsino mixings. This allows for a large annihilation cross-section into the lightest CP-even plus CP-odd scalars, $\chi_1^0 + \chi_1^0 \rightarrow h_1 + a_1$. As explained below, it is technically natural for a CP-odd scalar in the NMSSM to be light, and this restricts the subsequent decays to $a_1 \rightarrow \mu^+ \mu^-$. Hence, a flux of energetic positrons is obtained, while kinematics prevents the production of anti-protons, in agreement with observations. The positron fluxes can only be brought in agreement with the data, if the mass of the heavier CP-odd scalar, a_2 , is dialed to be $m_{a_2} \approx 2m_{\chi_1^0}$. Then, neutralino annihilation proceeds through the resonant a_2 state, which

would also increase the intensity of monochromatic γ -ray lines [54]. This scenario exemplifies the possibilities allowed by the larger Higgs sector of the NMSSM, but the careful choice of parameters required for the resonant annihilations to occur opposes the initial motivation to go beyond the MSSM.

These models introduce further theoretical questions. For instance, the annihilation cross-section is more than two orders of magnitude larger *at all times*, so that a non-thermal production mechanism has to be invoked to match the observed DM density. Since a non-thermal neutralino in the MSSM is also capable of explaining the PAMELA signal [38], there would be little motivation to go beyond the MSSM. Furthermore, in the scenario presented in [16], the loop corrections to the mass of a_1 are not suppressed by any small parameter, so a fine-tuning is required to achieve the sub-GeV mass in their parameter set that primarily produces muons in dark matter annihilation. The neutralino is also required to be less than the top mass, which may present a difficulty in fitting the shape of the PAMELA spectrum.

A different possibility, considered in [17], is that the neutralino could have a sizeable singlino component in the NMSSM. Annihilations would still proceed to the lightest scalars $h_1 + a_1$, both of which would now be mostly singlet-like, not just a_1 . Due to its very small couplings to all quarks, leptons and gauge bosons, a singlet-like h_1 is not bound by the LEP-II limit, $m_{H_{SM}} \gtrsim 114$ GeV, and could in fact be much lighter. Such a light scalar would naturally enhance the rate of neutralino annihilations in the Galaxy through the Sommerfeld enhancement, without the need of resonant annihilations and a non-standard cosmological evolution. Hence, in this setting all the ingredients of the DM scenarios engineered to reproduce the PAMELA signal [9, 12, 44] would be realized in a framework motivated *independently* from considerations of naturalness of the electroweak interactions. One should still make sure, however, that this does not require particular choices of the parameters to solve the μ -problem, which was the main motivation to go beyond the MSSM [65].

For a sufficient enhancement of the DM annihilation cross-section, the mass of the lightest CP-even scalar, h_1 , can be estimated as $m_{h_1} \lesssim \kappa^2 m_{\chi^0}/4\pi$, where κ is the trilinear coupling in Eq. (1). The anomalous trend in the positron fraction reported by PAMELA extends up to energies of ~ 100 GeV, which also sets the (minimum) mass of the neutralino. For moderate values of $\kappa \lesssim 1$ the mass of h_1 should be roughly $m_{h_1} \lesssim 10$ GeV (more details can be found in [9, 17]). Since the decay of the lightest CP-odd scalar, a_1 , should yield mostly charged leptons ($e^\pm$ or $\mu^\pm$), we demand $m_{a_1} \lesssim 1$ GeV. We also require that the μ term is

dynamically generated as in Eq. (2).

The parameter space of the NMSSM defined by Eq. (1) can be studied with the package NMSSMTools [66], which calls MicrOMEGAS[67] to calculate the relic density [55, 56]. Given a point in the NMSSM parameter space, the program suites check its viability against negative particle searches and rare-decay bounds from accelerators. We performed a number of scans, both over random points and on grids, in different regions of parameter space. For instance, in the region defined above, which is the region considered by [16], we randomly selected one million points that had $\lambda < 0.6$, with a flat distribution, and $\kappa < \lambda$. We fixed the soft terms A_λ and A_κ to have an exponential distribution peaked at zero, with a width of 10 GeV, to attempt to take advantage of a $U(1)_R$ symmetry that makes a pseudoscalar light, as in [16]. We also fixed $\tan\beta$ between 2 and 10, and μ between 100 and 240 GeV, and we randomly assigned all free signs to be positive or negative. The results demonstrate the difficulty in finding valid models. Approximately 0.2% of the parameters passed all present experimental constraints. Of these, none had a pseudoscalar below 1 GeV. Additionally, the neutralino had a mass of order the light scalars, $\mathcal{O}(10 \text{ GeV})$ rather than the required 100 GeV or greater. The spectrum of points that passed LEP and other constraints is shown in Figure 1.

FIG. 1: Values of the mass of the light pseudoscalar and the neutralino for parameter sets that pass constraints for the scan described in the text.

On the other hand, non-scale invariant terms in the superpotential were allowed in [17]. Including supersymmetric mass and tadpole terms, $\mu\hat{H}_u\hat{H}_d + \frac{1}{2}\mu'\hat{S}^2 + \xi_F\hat{S}$, it is possible

to viable points in this extended parameter space [18]. Even though, some of these terms are non-vanishing in various scenarios, they contradict the theoretical motivation for the NMSSM that the μ -term should be dynamically generated as in Eq. (2). We cannot exclude the possibility that a more thorough scan might reveal a valid region that meets our stricter requirements, but the general considerations below should illustrate the difficulties for a generic natural extension of the MSSM.

Light CP-odd scalars can easily appear in the NMSSM in the form of (pseudo-)Nambu-Goldstone bosons associated to approximate global symmetries. Both, in the R-symmetry limit, $A_\lambda, A_\kappa \rightarrow 0$, considered in [16–18], and in the Peccei-Quinn (PQ) limit, $\kappa \rightarrow 0$, on which we focus below, axion-like particles would be naturally present in the spectrum. Concrete scenarios exist (as reviewed in e.g. [51, 52]), in which this symmetries are explicitly broken, yet the axion remains light. The anti-proton constraints can, thus, be naturally met in the NMSSM.

There is no symmetry, however, that prevents the mass of the CP-even scalar, h_1 , from growing above the scale required for the Sommerfeld enhancement to be effective. In fact, as shown in Section III, requiring that the μ -parameter is generated as in Eq. (2) and that the lightest neutralino be heavier than ~ 100 GeV, cannot be simultaneously achieved while keeping $m_{h_1} \lesssim 10$ GeV. If we allow for non-scale invariant terms in the superpotential as in [17, 18], the lightest scalar is no longer linked to the electroweak-scale μ -term and can be lighter. However, this is not a natural outcome of singlet extensions of the MSSM, and requires the tuning of the parameters.

The main reason to include a light CP-even scalar is to enhance the annihilation cross-section in the low velocity limit, so that the positron fluxes from annihilations in the Galaxy can be large enough, while obtaining the right relic density from thermal freeze-out at the time of decoupling. As outlined in [9, 42, 43], such a light particle mediates long range forces that generate the non-perturbative Sommerfeld enhancement. A light vector particle also results in long-range forces, and this was in fact the first scenario in which the importance of this effect for DM was studied [42]. Other possibilities, such as CP-odd mediator particles, have been dismissed, since they do not give rise to spin-independent long range interactions *at tree level*. However, since pseudo-scalars do give rise to long-range forces at the one loop level [57], this conclusion should not necessarily apply in the non-perturbative regime. Indeed, as shown in [58], (pseudo-)Nambu-Goldstone bosons can cause

a Sommerfeld enhancement. As discussed above, we do have light pseudo-scalars in our spectrum, and we might ask whether lifting the limit on the mass of the h_1 , allows a DM explanation to the PAMELA observations, while abiding to Eq. (2).

Unfortunately, we find that this is not sufficient. In order to generate a splitting between the scalar and fermion components of the $\hat{S}$ superfield, in general we need to increase the mixing with the component of $\hat{H}_u$ and $\hat{H}_d$ by increasing λ . However, this also increase the magnitude of radiative corrections to the mass of the light scalars, requiring a high-degree of fine-tuning to maintain a sub-GeV pseudoscalar mass. One might hope to escape this problem by introducing additional superpotential terms, as in [17], however a subsequent study of the parameter space by [18] found that this scenario requires $\lambda \sim 10^{-3}$, a small coupling with no clear origin.

The previous discussion shows the difficulties in constructing a DM sector that allows an explanation of the rising positron fraction, and that is motivated by naturalness considerations of the electroweak interactions. A possible solution, with only scale invariant terms, was put forward in [12], where it was noted that an additional singlet could be added to the PQ-limit of the NMSSM. In the following we consider an scenario in the spirit of [12], and study the restrictions imposed by Eq. (2). In addition, we note that a similar superpotential was proposed in [59] to extend the NMSSM by a right-handed neutrino superfield, which serves as a suitable thermal dark matter candidate. As the motivation in [59] is not to explain observations made by PAMELA, the authors examine a different region of parameter space and an additional superfield coupling that is not relevant for our purposes.

III. ADDING A DARK MATTER SINGLET

Following from the above consideration of the NMSSM, we argue that a supersymmetric model that is not fine-tuned and contains leptophilic dark matter annihilation requires extending the MSSM by more than one field. Here we will consider the simplest case: the MSSM with an additional two superfields: a gauge singlet $\hat{S}$, as in the NMSSM, and an additional singlet $\hat{\Psi}$ that will serve as dark matter. In our arrangement, the $\hat{S}$ and $\hat{\Psi}$ together form a dark sector that is moderately secluded from the MSSM fields. While at first glance this theory may appear to be overly general, we will show below that observations and naturalness significantly restrict the allowed couplings.

To naturally generate a light pseudoscalar, we will take the $U(1)_{PQ}$ limit of the NMSSM, but will include an explicit symmetry breaking term κ . We take this limit both because it generates a light pseudoscalar with a controllable mass, and because that small mass is more stable against radiative corrections than the one provided by $U(1)_R$ symmetry. We assume the $\hat{\Psi}$ superfield has a $\mathbb{Z}_2$ symmetry which will guarantee a stability.

The superpotential of this theory is

$$W = \frac{\xi}{2} \hat{S} \hat{\Psi}^2 + \lambda \hat{S} \hat{H}_u \hat{H}_d + \frac{\kappa}{3} \hat{S}^3, \quad (3)$$

where $\hat{S}$ is the singlet of the NMSSM, and $\hat{H}_u$ and $\hat{H}_d$ are electroweak Higgs doublets, as in the MSSM. The new superfield $\hat{\Psi}$ consists of a fermionic component ψ , which will be a stable dark matter candidate, and complex scalar ϕ . We have not included the other matter fields of the MSSM, which are not relevant here. The corresponding scalar soft terms are

$$V_{\text{soft}} = \frac{\xi}{2} A_\xi S \phi^2 - \lambda A_\lambda S H_u^0 H_d^0 + \frac{\kappa}{3} A_\kappa S^3 + \text{h.c.}, \quad (4)$$

where we have dropped electrically charged components. Since κ is a small breaking of the $U(1)_{PQ}$ symmetry, we will take $\kappa \ll 1$. The typical sizes of the other parameters are discussed below.

As in the NMSSM, we require that the effective μ parameter given in (2) is of order the electroweak scale. Electroweak symmetry breaking does not generate a VEV for the scalar partner of the dark matter, ϕ . The consistency of this minimum can be checked by examining the eigenvalues of the Hessian for the scalar potential. In this paper we will not study the global structure of minima.

IV. MASS SPECTRUM

Having defined the theory, we will turn our attention to the mass spectrum of the theory in the presence of the additional states. We will denote the real scalar and pseudoscalar components of the ϕ and S fields with the subscripts s and a , respectively, and use the usual notation for the Higgs VEVs,

$$\langle H_u^0 \rangle = v_u, \langle H_d^0 \rangle = v_d, \quad (5)$$

where $v_u^2 + v_d^2 = v_{\text{EW}}^2$. In reference to the MSSM, it will be convenient to define an effective B parameter,

$$B = A_\lambda + \kappa \langle S \rangle = A_\lambda + \kappa \frac{\mu}{\lambda}. \quad (6)$$

The CP-even mass matrix, in the basis (H_d, H_u, S_s, ϕ_s) , is given by

$$M_{RS}^2 = \begin{pmatrix} g^2 v_d^2 + B\mu \frac{v_u}{v_d} & v_u v_d (2\lambda^2 - g^2) - B\mu & 2\lambda\mu v_d - v_u(\lambda B + \kappa\mu) & 0 \\ & g^2 v_u^2 + B\mu \frac{v_d}{v_u} & 2\lambda\mu v_u - v_d(\lambda B + \kappa\mu) & 0 \\ & & v_u v_d \left(\frac{\lambda^2 B}{\mu} - \kappa\lambda \right) + \kappa A_\kappa \frac{\mu}{\lambda} & 0 \\ & & & \lambda\xi v_u v_d + \xi A_\xi \frac{\mu}{\lambda} + \kappa\xi \frac{\mu^2}{\lambda^2} + \xi^2 \frac{\mu^2}{\lambda^2} \end{pmatrix} \quad (7)$$

where we drop terms of $\mathcal{O}(\kappa^2)$.

The Higgs sector contains a neutral massless Goldstone mode, G , that becomes the longitudinal mode of the Z boson. This can be rotated away, leaving a single physical Higgs pseudoscalar from the MSSM, A . After performing this transformation, the CP-odd mass matrix, in the basis (A, S_a, ϕ_a) , is given by

$$M_{IS}^2 = \begin{pmatrix} \frac{B\mu(v_d \cos\beta + v_u \sin\beta)^2}{v_u v_d} & (B\lambda - 3\kappa\mu)(v_d \cos\beta + v_u \sin\beta) & 0 \\ & \frac{\lambda v_u v_d}{\mu}(B\lambda + 3\kappa\mu) - 3\frac{\kappa}{\lambda} A_\kappa \mu & 0 \\ & & \frac{\xi}{\lambda^2}(v_u v_d \lambda^3 - \mu(\lambda A_\xi + \kappa\mu - \xi\mu)) \end{pmatrix} \quad (8)$$

The neutralino mass matrix is extended from the MSSM by the fermionic components of the superfields S and Ψ . In the basis $(\tilde{B}, \tilde{W}^0, \tilde{H}_d, \tilde{H}_u, \tilde{S}, \psi)$, it is given by

$$M_F = \begin{pmatrix} M_1 & 0 & -\frac{g_1 v_d}{\sqrt{2}} & \frac{g_1 v_u}{\sqrt{2}} & 0 & 0 \\ & M_2 & \frac{g_2 v_d}{\sqrt{2}} & -\frac{g_2 v_u}{\sqrt{2}} & 0 & 0 \\ & & 0 & -\mu & -\lambda v_u & 0 \\ & & & 0 & -\lambda v_d & 0 \\ & & & & 2\frac{\kappa}{\lambda}\mu & 0 \\ & & & & & \frac{\xi}{\lambda}\mu \end{pmatrix} \quad (9)$$

We will label the resulting scalar and pseudoscalar mass eigenstates with h_i and a_i respectively, ordered from lightest to heaviest. Similarly, we will label the neutralinos with $\tilde{N}_i$. To avoid confusion, we will continue to label the states of Ψ with ψ and ϕ , since these states are the same as their flavor states.

We will be interested in the region of parameter space where λ is small, but not unnaturally so. In the PQ limit, which we consider, κ is expected to be very small, but λ is not. In this case, the lightest scalar and pseudoscalar, h_1 and a_1 , are composed primarily of singlet S states. The Higgs with significant couplings to the Standard Model are h_2 , h_3 and a_2 . The lightest neutralino, $\tilde{N}_1$, is composed primarily of singlino $\tilde{S}$. Since the lightest states are all only slightly mixed with other Higgs, their coupling are very nearly those of the $\hat{S}$ flavor states.

The behavior of dark matter in this theory primarily depends on the value of the masses of the light particles. In the region of parameter space we will look at below, the Sommerfeld enhancement is generated primarily by a_1 . The lightness of this particle also kinematically enforces the creation of light leptons rather than baryons in dark matter annihilation. To leading order in κ and λ , the tree-level mass of this particle is

$$m_{a_1}^2 = \frac{9}{2} v_{\text{EW}}^2 \kappa \lambda \sin 2\beta. \quad (10)$$

The lightest scalar, h_1 , has a leading mass m_{h_1} that is independent of κ and so is generically unsuppressed relative to m_{a_1} . The more complicated mixing of the 3×3 CP-even mass submatrix does not lend itself to compact expression for this mass. To leading order in λ , the mass is given by

$$m_{h_1}^2 = \frac{-\lambda^2 \sec^2 2\beta}{2g^2 A_\lambda \mu} \left(8A_\lambda \mu^3 - 8A_\lambda^2 \mu^2 \sin 2\beta + 2A_\lambda \mu (A_\lambda^2 - 2g^2 v^2) \sin^2 2\beta + g^2 v^2 (A_\lambda^2 + 4\mu^2) \sin^3 2\beta \right). \quad (11)$$

The hierarchy of scalar and pseudoscalar masses is illustrated for typical values in Figure 2.

Positivity requirements for the mass place restrictions on the allowed values of the other coupling constant and soft terms. This relationship further implies the existence of a maximal value for m_{h_1} once the dimensionless coupling constants are fixed. An example of this for typical values is given in Figure 3. A_λ is of the order of the typical soft breaking scale. A_κ is less relevant, as its contribution is suppressed by κ .

The scalar and pseudoscalar masses are shifted by loop corrections from the tree-level values given above. These corrections are suppressed by additional powers of λ and κ , plus loop factors. For $\lambda \lesssim 0.1$, these corrections are sufficiently small that they do not affect the results we present. In particular, the light pseudoscalar receives mass corrections that are less than a GeV. Note that this is true in the PQ-limit with small κ , but requires an

FIG. 2: Contour plots of the tree-level values of $m_{a_1}^2$ and $m_{h_1}^2$ as a function of κ and λ for the case of $\mu = 130$ GeV

FIG. 3: Values for the tree-level square mass of the light scalar, $m_{h_1}^2$, where $\mu = v_{EW}$, $\lambda = 0.1$, $\tan \beta = 4$ and $A_\lambda = 500$ GeV.

unnaturally small value of λ (which is not related to any enhanced symmetry) in the regions considered in [16–18].

The supersymmetric partner to these light scalars, $\tilde{N}_1$, typically has a mass of a few GeV that is intermediate between h_1 and a_1 . To leading order in λ , g_1 and g_2 , an approximation good to 10% or better, this particle has a tree-level mass

$$m_{\tilde{S}} = \frac{\lambda^2 v^2 (4M_1 M_2 \mu \sin 2\beta - 2(g_2^2 M_1 + g_1^2 M_2) v^2 \cos^2 2\beta)}{4M_1 M_2 \mu^2}. \quad (12)$$

Finally, there is the mass of the dark matter itself. The fermion ψ is stable and has a mass that is fixed by $\langle S \rangle$ and the coupling ξ ,

$$m_\psi = \xi \frac{\mu}{\lambda}. \quad (13)$$

Note that if μ is near the electroweak scale, then μ/λ is $\mathcal{O}(\text{TeV})$ for the relevant values of λ . We then get a dark matter mass of $\mathcal{O}(100 \text{ GeV})$ or above for $\xi \gtrsim 0.1$.

V. DARK MATTER

Within the model described above, we identify several possible dark matter scenarios. First, we assume that supersymmetry breaking is gauge-mediated, so the true LSP of the theory is the gravitino. The stability of ψ is protected by an unbroken $\mathbb{Z}_2$ symmetry, which makes it a suitable heavy dark matter candidate. The ϕ_s and ϕ_a have mass that is typically somewhat larger, so can decay through the channel $\phi_{s,a} \rightarrow \psi \tilde{N}_1$. The $\tilde{N}_1$, the NLSP of the theory, will then decay to a gravitino and a singlet scalar.

Even if $m_\phi < m_\psi + m_{\tilde{N}_1}$, the ϕ can still decay to a gravitino and a ψ , either in tree-level processes with a virtual $\tilde{N}_1$, or in 1-loop processes with an h_1 or an a_1 in the loop. To avoid problems in the early universe, we assume either that ϕ is sufficiently massive to decay to ψ and $\tilde{N}_1$ on-shell, or that the suppressed processes allow the ϕ to decay prior to the BBN.

If the ϕ are long-lived due to suppressed decay processes, a careful consideration of the early universe is required. If a significant number of ϕ particles remain after freeze-out, a late decay to gravitinos after nucleosynthesis will ruin the successful predictions of early universe cosmology. However, the ϕ has additional self-annihilation channels generated by 3- and 4-point scalar interactions that tend to raise its cross-section significantly, and their relic density becomes irrelevant. If the ϕ mass is nearly degenerate with the ψ mass, then there may be additional cross-annihilation channels that will shift the ψ relic density from the values given below. This offers the interesting possibility of breaking the relationship of m_ψ and the relic density, both of which are set by ξ .

There is also the possibility that supersymmetry breaking is gravity-mediated. In this case, the singlino is the true LSP and absolutely stable. This is problematic in the model presented above, as the dominant channel for singlino self annihilation, to Higgs through an s-channel, scales as κ^2 , and so $\tilde{N}_1$ is overproduced thermally in the early universe. However,

in a slightly expanded version of the model, in which we allow dimensional superpotential terms, we can arrange for a $U(1)_{PQ}$ symmetry with non-infinitesimal κ . A version of this model was described in [17]. Here the self-coupling can be much larger, and we can arrange for a two-component dark matter system that is a mixture of the heavy ψ and the light $\tilde{N}_1$. Since this scenario requires an extended parameter set, we will not consider it further here.

We will make the new fields moderately secluded through a small, but natural, value of the coupling $\lambda \sim 0.1$. Above this value, the radiative corrections to the scalar masses shifts their values from the tree-level significantly. Below this value, the annihilation cross-section is suppressed, and the universe tends to overclose. After λ and μ are fixed, the coupling ξ is still free to fix both the dark matter mass and its annihilation cross-section. We will show below that $\xi \sim 0.4$ is an appropriate value. Our couplings are arranged in the loose hierarchy

$$\kappa \ll \lambda < \xi. \quad (14)$$

A. Relic Density

The relic dark matter is thermally produced in this scenario. While the coupling of the dark matter to the standard model fields is small, the coupling ξ of the dark matter particles to fields of $\hat{S}$ is essentially unconstrained. The value of this parameter fixes the annihilation cross-section, and it is notable that the same values that produce dark matter mass of $\mathcal{O}(100 \text{ GeV})$ in (13) also yield the observed relic density.

A number of annihilation channels are potentially relevant. There is an s-channel process mediated by h_1 or a_1 with a two-particle final state consisting of a combination of scalars h_1 , a_1 , h_2 or h_3 . Higgsino production in this channel is possible, but suppressed by κ if it is allowed kinematically.

There are two relevant t- and u-channel processes. The first is mediated by ϕ and results in two $\tilde{N}_1$ particles in the final state. The second is mediated by ψ and results in an h_1 and a_1 . The processes that are not λ -suppressed are shown in Figure 4.

When comparing the cross-sections of the various channels, one might expect that the Higgs production is suppressed by a large amount, as these matrix elements appear to be proportional to λ^2 . However, some channels are enhanced by $\langle S \rangle$, which is proportional to λ^{-1} , and they are only suppressed by one power of λ . Since we do not have $\xi \gg \lambda$, we can

FIG. 4: Processes that contribute to the annihilation of ψ which are unsuppressed by κ .

not *a priori* ignore Higgs production during ψ annihilation.

We implemented this model and evaluated cross-sections within CalcHEP [60] and found the annihilations are dominated by the process $\psi\psi \rightarrow \tilde{N}_1\tilde{N}_1$. This non-relativistic cross-section, as a function of μ and ψ , is shown in Figure 5. The process $\psi\psi \rightarrow h_1a_1$ provides a significant subdominant contribution, approximately 10% of the previous process. A plot of the cross-section for the same region of parameter space is given in Figure 6.

Higgs production s-channel processes to a_1h_2 and a_1h_3 are typically suppressed by another factor of 10^2 from h_1a_1 production, and so can be safely ignored for the parameter space of interest.

Finally, we note that in this model the secluded sector may decouple from the other fields of the NMSSM and undergo a separate evolution in the early universe. If there are additional heavy degrees of freedom in the secluded sector that come out of equilibrium during this period, the temperature of the secluded sector will diverge from the temperature of the photons. This shift in temperature may alter the relationship of cross-section and relic

FIG. 5: σv for the annihilation of $\psi\psi$ to $\tilde{N}_1\tilde{N}_1$ in units of cm^3/s with $\lambda = 0.1$. The gray region shows the cross-section that generates the observed relic abundance.

FIG. 6: σv for the annihilation of $\psi\psi$ to h_1a_1 in units of cm^3/s with $\lambda = 0.1$.

density through an effect like the one described in [11]. Here ψ and a_1 would, respectively, play the role of X and Y from that paper. The Z_i is provided by ϕ_a and ϕ_s , and the temperature difference could be enhanced by including additional heavy unstable singlets.

B. Galactic Annihilations

In the galaxy, the effective cross-section for dark matter annihilation is increased due to the Sommerfeld effect. In our model, this effect arises predominantly from the exchange of the pseudoscalar a_1 , as described in [58].

As described in the preceding section, dark matter annihilation will produce $\tilde{S}$ particles that quickly decay to a_1 , or will produce a_1 and h_1 directly. The zero-temperature cross-sections, relevant in the galaxy, for dark matter annihilation to these particles have fairly simple approximate analytic expressions,

$$\sigma v_{\psi\psi \rightarrow \tilde{N}_1 \tilde{N}_1} = \frac{\xi^2 \lambda^2}{128\pi\mu^2} + \mathcal{O}(\lambda^4), \quad (15)$$

$$\sigma v_{\psi\psi \rightarrow h_1 a_1} = \frac{\xi^2 \lambda^2}{2048\pi\mu^2} + \mathcal{O}(\lambda^4). \quad (16)$$

When making numerical calculations, we do not use these approximate expressions, but instead keep all orders of λ and T .

The h_1 and a_1 produced in these annihilations have small mixings with the MSSM Higgs that will cause them to decay to the heaviest allowed states. The mass of a_1 , given (10), can be kept sub-GeV for sufficiently small κ , and loop corrections to the mass can be kept under control with a moderately small λ . This allows kinematic enforcement for the production of light leptons during annihilation, as in the mechanism of [9, 11] and others. This can give rise to a flux of positrons that is measurable about the modeled astrophysical background, as was observed in the PAMELA experiment [4].

The h_1 typically has a mass above the threshold for baryon production, and so will contribute to the anti-proton flux. However, the cross-section of this subdominant annihilation to baryons is sufficiently small that the excess of anti-protons will lie well within the current experimental uncertainty.

We estimate the positron spectrum within the energy range measured by PAMELA by using approximate solutions to the diffusion equation,

$$\dot{f} - K(E) \cdot \nabla^2 f - \frac{\partial}{\partial E} (b(E)f) = Q, \quad (17)$$

where f is the positron distribution, K is a diffusion constant, b is an energy loss coefficient, and Q is the positron source term. For the case of cylindrical symmetry, an analytical

solution for the positron flux observed at Earth is given by

$$\Phi(E) = B \frac{v_{e^+}}{8\pi b(E)} \left(\frac{\rho_\odot}{M} \right)^2 \int_E^M dE' \sigma v \frac{dN_{e^+}}{dE_{e^+}} I(\lambda_D(E, E')), \quad (18)$$

where K is the diffusion coefficient, $\rho_\odot$ is the dark matter density at our solar system, I is the halo profile, and λ_D is the positron diffusion length. An overview of the approximate solution to this equation in the presence of cylindrical symmetry is given in [61], and we use the “medium” NFW dark matter profile from that paper.

The electrons and positrons are created at the end of a chain decay. In the dominant process, the ψ annihilation produces two $\tilde{N}_1$ particles, each of which decays to a gravitino and an a_1 . Depending on its mass, the a_1 decays to muons or electrons. We numerically calculate the resulting spectrum, dN_{e^+}/dE_{e^+} by selecting random directions for each step of the decay, isotropic in the decaying particle’s rest frame, and then boost the electron 4-momentum to the galactic frame. We perform 10^5 trails, and fit the resulting spectrum to the three-parameter function $c_1 E_{e^+}^{c_2} + c_3$, which yields excellent agreement. We perform this procedure for each combination of μ , λ and ξ that are used below.

For each point in parameter space, we fit the positron spectrum generated by dark matter annihilations to the PAMELA spectrum with an overall scaling “boost factor.” The observed spectrum, originally reported in [4], has recently been updated using a new statistical method [5]. The method has resulted in a spectrum that is slightly softer, which suggests a larger dark matter mass and reduced boost factors. We fit our model to both versions of the data. A typical spectrum that results from the numerical fitting procedure is shown in Figure 7. The boost factors required may be a combination of enhancement in the local annihilation due to structure within the dark matter halo, and the pseudoscalar Sommerfeld effect. A plot of the required boost factors across a portion of parameter space is given in Figure 8. The large hierarchy between pseudoscalar mass and dark matter mass, $m_{\tilde{N}_1}/m_{a_1} \sim \mathcal{O}(500)$ easily provides the boost factors required for $\mu \lesssim 100$ GeV.

VI. DISCUSSION AND CONCLUSIONS

Our exploration of the dark matter sector in singlet, $\hat{S}$, extensions of the MSSM shows that explaining the anomalous positron fluxes observed by PAMELA with neutralino annihilations is not possible without a carefully tuned choice of parameters, in regions where the

FIG. 7: The positron spectrum observed near Earth, from the reanalyzed PAMELA data given in [5], shown as a ratio of positrons to the sum of positrons and electrons. The points are the spectrum observed by PAMELA, and the line is the spectrum generated by the present model for the particular choice $\mu = 70$ GeV, $\xi = 0.3$ and $\lambda = 0.1$ (which yields $m_\psi = 210$ GeV), and a boost factor of 42.

FIG. 8: The boost factor required, as a function of ξ , to fit the model to the PAMELA spectrum for $\lambda = 0.1$. The solid curves result from a numerical fit to the newer PAMELA [5], and the dashed curves result from a numerical fit to the original PAMELA spectrum [4]. Each neighboring pair of solid and dashed curves is for a different value of μ . From bottom to top, these are $\mu = 70, 90, 110$ GeV.

original particle physics motivation for these extensions is lost.

In the NMSSM, the simplest such extension that addresses the little-fine tuning and the μ problems, it is hard to reconcile a neutralino at the electroweak scale, $m_{\tilde{N}} \gtrsim 100$ GeV, with the light (pseudo-)scalars that are required to avoid large anti-proton signals, and to enhance the present day annihilation rate. Indeed, this can only be achieved by adding non-scale invariant terms to the superpotential. These terms could emerge from an unspecified higher energy theory, but then the scale of the μ term cannot be explained in the framework of the NMSSM.

We have showed how adding a dark matter singlet superfield, $\hat{\Psi}$, to the NMSSM in the PQ limit, makes it possible to obtain a large positron flux from DM annihilations, without an unnatural choice of parameters. The DM, ψ , annihilates primarily into a pair of NMSSM singlino-type neutralinos. These in turn produce pairs CP-odd higgs, which can be very light in the PQ-limit and would mostly generate light leptons upon decay. Anti-protons in this scenario are only generated by an annihilation to light scalars that include the h_1 , not in the annihilation to neutralinos. Hence the lack of antiprotons in the spectrum is naturally generated.

A similar scenario had been considered in [12], but our setup differs in a few important aspects. Our DM is a Majorana fermion, whose stability is ensured by a $\mathbb{Z}_2$ symmetry, that annihilates primarily into a pair of NMSSM singlinos, whereas vector-like DM annihilation can be dominantly to $h_1 + a_1$ [12]. Positrons are generated by the decay of the a_1 , which appears further down in the reaction chain in our setup, and resulting in a softer spectrum. The updated positron spectrum is softer at high energies [5] than suggested by initial estimates, and we have shown how our model can fit the data with *natural* values of the parameters in the DM sector, $\xi \lesssim 1$, and in the electroweak sector, $\lambda \lesssim 1$ and $\mu \sim 100$ GeV. The excess in the positron fraction could extend to higher energies, and there have been conflicting measurements of a large bump by ATIC [62], which is not seen by Fermi [63]. Systematic uncertainties make these measurements challenging, and more experimental work needs to be done to clarify the spectrum above the PAMELA cut-off [64]. In view of these facts, we have not attempted to fit any of the higher energy experiments in our model. Let us briefly mention, that we can allow masses for the DM particle that are large enough to create positron fluxes at much larger energies. This is not the case in other scenarios, where going beyond the top quark mass is problematic [16]. We also predict a softer spectrum than in

models where the positrons appear earlier in the annihilation chain [9, 12, 16, 17].

The annihilation rate in the galactic halo should be larger than at the time of decoupling, and previous proposals have frequently invoked a light scalar particle to achieve this boost [9, 12, 17, 44]. However, we have explicitly shown in a particular well-motivated setup that CP-even scalars are not expected to be light enough to generate the required Sommerfeld enhancement. Unlike previous studies, we do not have any in the spectrum, but we have pointed out that the light CP-odd higgs can also be used for this purpose. Hence, the relic DM is thermally produced in this scenario. While the theory may appear overly general, observations and naturalness considerations restrict the allowed couplings to a narrow range. The coupling ξ of the DM particles to the singlet field S determines both the annihilation cross-section and the mass of the DM particles. It is remarkable that a value $\xi \sim 0.3$ produces the required $\mathcal{O}(100 \text{ GeV})$ mass, while it also yields the observed relic density. Hence, insisting on a DM particle that is motivated independently by particle physics naturalness considerations we have delineated a viable scenario that can account for the PAMELA observations without requiring a fine-tuning of the parameters, and addressing at the same time some of the shortcomings of the MSSM.
